Rational design of new NO and redox sensitivity into connexin26 hemichannels

1. Summary

CO2 directly opens hemichannels of connexin26 (Cx26) by carbamylating K125, thereby allowing salt bridge formation with R104 of the neighbouring subunit in the connexin hexamer. The formation of the inter-subunit carbamate bridges within the hexameric hemichannel traps it in the open state. Here, we use insights derived from this model to test whether the range of agonists capable of opening Cx26 can be extended by promoting the formation of analogous inter-subunit bridges via different mechanisms. The mutation K125C gives potential for nitrosylation on Cys125 and formation of an SNO bridge to R104 of the neighbouring subunit. Unlike wild-type Cx26 hemichannels, which are insensitive to NO and NO2, hemichannels comprising Cx26K125C can be opened by NO2 and NO donors. However, NO2 was unable to modulate the doubly mutated (K125C, R104A) hemichannels, indicating that an inter-subunit bridge between C125 and R104 is required for the opening action of NO2. In a further test, we introduced two mutations into Cx26, K125C and R104C, to allow disulfide bridge formation across the inter-subunit boundary. These doubly mutated hemichannels open in response to changes in intracellular redox potential.

2. Introduction

The human genome contains 21 connexin genes [1]. Connexins are one of the main gene families that can form gap junctions. Each gap junction is made of two hemichannels, comprising six connexin subunits, one in each plasma membrane of two adjacent cells. The hemichannels dock to form a continuous passageway linking the cytoplasm of the coupled cells that permits transfer of ions and small molecules. In addition to this canonical function of connexins as gap junctions, undocked hemichannels can also have physiological functions [2,3]. We have shown that hemichannels of three closely related β connexins, Cx26, 30 and 32, can be opened by CO2 [4]. In the case of Cx26, we have established that this is a direct action in which CO2 binds covalently to K125 via a carbamylation reaction [5]. The carbamylated residue can then form a salt bridge to the neighbouring subunit in the hexamer [5]. This opens the hemichannel, and allows release of ATP, which is an important biological signalling molecule [6]. The CO2-dependent opening of Cx26, and consequent release of ATP, is a key mechanism in the regulation of breathing by CO2 [6].

In this paper, we demonstrate that it is possible to increase the range of molecules that can alter the gating of Cx26 via a rational mutational strategy. Given that formation of a bridge between residues 125 and 104 in adjacent subunits seems vital for CO2-mediated hemichannel opening [5], we have explored whether alternative mechanisms of bridge formation might also be effective. NO is an important gaseous signalling molecule that is produced by cells and can act via activation of a guanylate cyclase. NO can also signal via a nitrosylation reaction, whereby cysteine residues become converted to SNO groups (figure 1) [7]. We have tested whether the mutation K125C has the ability to support NO/NO2-mediated channel opening. If C125 were to be nitrosylated, the resulting SNO group would have the potential to form an inter-subunit salt bridge.

bridge with Arg104 [5] (figure 1) and, if our model is correct, Cx26K125C should be opened by NO/NO₂. We have additionally demonstrated, in hemichannels with the mutations K125C and R104C, that disulfide bridge formation between subunits will allow hemichannel opening in response to changes in intracellular redox.

3. Methods

3.1. Mutant connexin production

Cx26K125C and Cx26K125C,R104C mutants were produced from wild-type Cx26 in a Puc19 plasmid via the Quikchange protocol. The primers used were as follows: Cx26K125C forward, 5' CGA AGA GAT CAA AAC CCA GTG CGT CCG TAT CGA AGG GTC CC 3'; reverse, 5' GGG ACC CTT CGA TAC GGA CGC ACT GGG TTT TGA TCT CTT CG 3'; for Cx26K125C,R104A, a second set of primers was used to introduce the R104A mutation into Cx26K125C—forward, 5' GGC CTA CCG GAG ACA CGA AAA GAA ATG CAA GTT CAT GAA GGG AGA G 3'; reverse, 5' CTC TCC CTT CAT GAA GAA GCA TTT CTT TTC GTG TCT CCG G 3'. The DNA produced was processed using DPN1 digest and bacterial transformation. DNA mutation was confirmed by genomic sequencing. The Cx26 mutants were subcloned into a pCAG-GS vector for mammalian cell transfection.

3.2. HeLa cell culture

HeLa cells were cultured by standard methods in DMEM and 10% FCS with addition of 3 mM CaCl₂. For experimentation, cells were plated onto coverslips at a density of 5 x 10⁴ cells per well. Transient transfections were performed using the Genejuice protocol.

3.3. Dye loading protocols

3.3.1. Solutions used

Control saline: 124 mM NaCl, 26 mM NaHCO₃, 1.25 mM NaH₂PO₄, 3 mM KCl, 10 mM d-glucose, 1 mM MgSO₄, 1 mM CaCl₂.
3.3.2. Sensitivity to NO2 and NO donors

Coverslips plated with HeLa cells transiently transfected with Cx26K125C, Cx26K125C,R104A or Cx26WT were exposed to control saline containing 200 μM carboxyfluorescein (CBF) and 100 μM NaN2 or the NO donors 2-(N,N-diethylamino)-diazenolate 2-oxide (DEA-NONOate, 100 or 10 μM) or sodium nitroprusside (SNP, 100 μM), for 10 min. This was followed by saline with 200 μM CBF for 5 min to allow the hemichannels to close in the absence of a stimulus and thus reduce loss of dye from the cells through any open hemichannels, and a 30 min wash with saline (in the absence of CBF) to ensure that all dye was removed from the outside of the cells. The cells were then immediately imaged to quantify dye loading.

To establish whether the guanylate cyclase blocker H-[1,2,4]oxadiazolo[4,3-a]quinoxalin-1-one (ODQ) could affect the modulation of Cx26K125C by DEA-NONOate, ODQ at 3 μM was pre-applied in control saline for 15 min, and present during the application of the DEA-NONOate in the presence of CBF. This was then followed by the washing procedure as described above.

The control comparison used to establish any baseline loading in the absence of a stimulus followed exactly the same protocol, but no NaN2 or NO donors were present. Thus, the HeLa cells were exposed to 200 μM CBF in control saline for 15 min, followed by 30 min of washing.

The zero Ca2+ positive control involved exposure of Cx26 (mutant or wild-type) expressing cells to saline containing 200 μM CBF for 10 min. This was followed by control saline with 200 μM CBF for 5 min and 30 min of washing with saline. We have previously shown that non-transfected HeLa cells, or HeLa cells transfected with an empty vector have no responsiveness to the zero Ca2+ stimulus [5,8]. Only batches of transfected cells that successfully demonstrated dye loading in response to zero Ca2+ were included in the analysis.

3.3.3. Redox sensitivity

We used two solutions to manipulate intracellular redox: ‘reduced saline’ contained 4 mM N-acetyl-L-cysteine (NAC) and ‘oxidized saline’ contained 1 mM L-buthionine sulfoximine (BSO). The HeLa cells were exposed for 5 min to reduced saline, and then transferred to oxidized saline plus 200 μM CBF for 10 min. They were then washed with reduced saline plus CBF for 5 min before being washed for 30 min in reduced saline.

The no-stimulus control to assess baseline loading was exposure of the cells to 200 μM CBF in reduced saline for 15 min, followed by 30 min of washing in reduced saline.

Each experiment was independently repeated (i.e. separate transfections on different batches of cells on different days) at least five times as noted in the relevant figure legends.

Figure 2. Dye loading protocols used to test the sensitivity of HeLa cells expressing wild-type and mutant Cx26 hemichannels to nitrite, NO donors and changes in redox potential. NAC, N-acetyl L-cysteine; BSO, L-buthionine sulfoximine; CBF, carboxyfluorescein.
median values from each independent repetition via the Mann–Whitney U-test. As we have used non-parametric statistical comparisons, we show the median values together with the upper and lower quartiles in the figures.

3.5. Patch clamp recordings

Coverslips containing non-confluent cells were placed into a perfusion chamber at 28°C in sterile filtered standard saline. Standard patch clamp techniques were used to make whole cell recordings and outside out or inside out membrane patch recordings. For whole cell patch clamp, the intracellular fluid in the patch pipette contained: K-glucuronate 130 mM, KCl 10 mM, EGTA 10 mM, CaCl₂ 2 mM, HEPES 10 mM, pH 7.3, and adjusted to 295 mOsm with pure H₂O (dilution no more than 2%). All whole-cell recordings were performed at a holding potential of −40 mV with regular steps of 5 s, every 10 s, to −50 mV to assess whole cell conductance.

4. Results

4.1. The mutation K125C creates an NO₂⁻ and NO-sensitive hemichannel

We examined the gating of Cx26 hemichannels via an established assay, whereby loading of CBF into Cx26-expressing HeLa cells is a measure of hemichannel opening [5]. We found that 100 μM nitrite caused dye loading in Cx26K125C-expressing HeLa cells (p = 0.008 compared with background control, figure 3a,b). The extent of dye loading in 100 μM nitrite was very similar to that caused by the zero Ca²⁺ positive control, suggesting that the nitrite stimulus was very effective at opening the hemichannels (figure 3d).

Importantly, we found that HeLa cells expressing wild-type Cx26 had no endogenous sensitivity to nitrite, as no increase in dye loading was seen (figure 3c,e). As a positive control to test for functional hemichannels, we used a zero Ca²⁺ challenge, which we have previously shown has no effect on dye loading in parental HeLa cells which have no connexin expression [5,8]. The zero Ca²⁺ stimulus was very effective at causing dye loading in HeLa cells expressing wild-type Cx26 (figure 3c,d,e), demonstrating that functional wild-type hemichannels are present. The lack of effect of NO₂⁻ must therefore be due to its inability to open the wild-type Cx26 hemichannels. Taken together, these results demonstrate that wild-type Cx26 does not respond to NO₂⁻ with channel opening, but that this new functionality can be conferred on Cx26 by the mutation K125C.

We next tested whether R104 was required for the modulation of CBF. We have previously demonstrated that the Cx26R104A is CO₂ insensitive as the loss of the arginine residue at this location prevents formation of the inter-subunit salt bridge with the carbamylated K125. In this doubly mutated variant, if C125 were to be nitrosylated it would be unable to form a salt bridge to A104. We found that HeLa cells expressing Cx26K125C,R104A did not exhibit dye loading in response to NO₂⁻ (figure 4a,b). However, the positive control of the zero Ca²⁺ stimulus evoked dye loading indicating that functional hemichannels were present (figure 4a,b). Overall, while Cx26K125C hemichannels exhibited robust sensitivity to NO₂⁻, neither Cx26WT nor Cx26K125C,R104A hemichannels displayed any sensitivity to NO₂⁻ (figure 4c). Thus, we conclude that both C125 and R104 are required for nitrite sensitivity.

NO donors are more usually used to demonstrate activation of the NO signalling pathway and nitrosylation. We therefore additionally tested two NO donors, DEA-NONOate and SNP. Both of these donors at 100 μM caused dye loading into HeLa cells expressing Cx26K125C (figure 5a). However, HeLa cells expressing wild-type Cx26 showed no such NO-evoked dye loading (figure 5b), indicating that this is a specific effect of the NO donors on HeLa cells expressing Cx26K125C. We also tested DEA-NONOate at a lower concentration (10 μM) and found that this too caused dye loading into cells expressing Cx26K125C (p = 0.016, n = 5, figure 5c). However, the extent of the dye loading was less compared with both the higher dose of DEA-NONOate and the zero Ca²⁺ control (figure 5c).

---

**Figure 3.** Cx26K125C hemichannels can be opened by NO₂⁻. (a) Images showing HeLa cells expressing Cx26K125C. In the control (left), the cells have been exposed to CBF in saline, and very little dye loading is seen. When the cells were exposed to CBF in the presence of 100 μM NO₂⁻, dye loading was observed. (b) Cumulative probability plots of pixel intensity (combined data from five independent repetitions) demonstrate the exposure to NO₂⁻ cause a rightward shift to higher pixel intensities in HeLa cells expressing Cx26K125C. (c) HeLa cells expressing wild-type Cx26 (Cx26WT) do not exhibit dye loading with NO₂⁻, nevertheless, the positive control of zero Ca²⁺, which opens hemichannels, results in dye loading of the HeLa cells expressing Cx26WT, demonstrating the presence of functional hemichannels in the membrane. Combined data from five independent repetitions. (d,e) Histograms of median pixel intensity (with lower and upper quartile error bars) for the effects of 100 μM NO₂⁻ and zero Ca²⁺ stimuli in Cx26K125C and Cx26WT, respectively.
In addition to nitrosylation, NO can signal via the activation of guanylate cyclase and the cGMP-dependent protein kinase. We therefore tested whether ODQ, a blocker of guanylate cyclase, affected the modulatory action of DEA-NONOate on HeLa cells expressing Cx26K125C. We found that 3 \( \mu \text{M} \) ODQ did not affect the degree of dye loading caused by 10 \( \mu \text{M} \) DEA-NONOate (figure 5c,d). We therefore conclude that guanylate cyclase does not contribute to the modulatory action of the NO donors on Cx26K125C.

4.2. The mutation K125C, R104C creates a redox-sensitive hemichannel

Disulfide bridges represent a further way in which a bridge between subunits at residues 125 and 104 could form. A disulfide bridge would be sensitive to intracellular redox as this would potentially reduce the disulfide bridge to break it apart or oxidize the cysteine SH groups to promote bridge formation. We therefore made a further variant of Cx26, Cx26K125C,R104A, to test whether we could create a redox-sensitive hemichannel.

We used L-BSO and NAC to manipulate the redox state of HeLa cells via altered intracellular concentrations of glutathione [9]. BSO inhibits \( \gamma \text{-glutamylcysteine synthase} \), an enzyme essential for glutathione synthesis [10]. BSO will therefore cause a decrease in the concentration of intracellular glutathione and will make the cell relatively oxidized and promote disulfide bridge formation [9]. Conversely, NAC, by acting as a precursor, can increase the intracellular concentration of cysteine, and thus enhance intracellular glutathione concentrations [11]. NAC will therefore make the cell more reduced and tend to break disulfide bridges [9].

We used dye loading in the presence of NAC as a reduced control, and transferred the cells to solutions containing BSO as the oxidized stimulus. Cells exposed to the reduced saline did not exhibit enhanced dye-loading (figure 6). However, when cells were exposed to the oxidized saline, there was a big increase in dye loading compared with control experiments (\( p = 0.021 \), figure 6). This redox sensitivity is not a property of wild-type Cx26, as HeLa cells stably expressing Cx26 showed no redox-sensitive dye loading (figure 6).

4.3. Patch clamp recordings demonstrate the kinetics of agonist sensitivity

To confirm the dye loading experiments, we performed whole cell patch clamp recordings from HeLa cells expressing wild-type Cx26, Cx26K125C and Cx26K125C,R104C. HeLa cells expressing wild-type Cx26 reliably responded to a CO2
Ca\textsuperscript{2+} median pixel intensity (histogram showing the median change in median pixel intensity caused by 10 \textmu M DEA-NONOate (both at 100 \textmu M) on dye loading in HeLa cells expressing Cx26\textsuperscript{K125C} or wild-type Cx26 (Cx26\textsuperscript{WT}) compared with the control, and the effect of zero Ca\textsuperscript{2+}. The donors do not cause dye loading in HeLa cells expressing Cx26\textsuperscript{WT}, but do in HeLa cells expressing Cx26\textsuperscript{K125C}—as shown by rightward shift of cumulative probability plots. The cumulative probability plots are from combined data for five independent repetitions of each condition. Inset shows the median change in median pixel intensity (n = 5) for the actions of DEA-NONOate and SNP (100 \textmu M) on Cx26\textsuperscript{K125C} and Cx26\textsuperscript{WT}. (c) A lower dose of DEA-NONOate (10 \textmu M) causes a smaller amount of dye loading compared with the zero Ca\textsuperscript{2+} control. The dye loading is unaffected by the guanylate cyclase inhibitor ODQ (3 \textmu M). (d) Summary histogram showing the median change in median pixel intensity caused by 10 \textmu M DEA-NONOate either on its own or with 3 \textmu M ODQ (n = 5, p = 0.421, Mann–Whitney U-test).

Figure 5. Cx26\textsuperscript{K125C} hemichannels can be opened by NO donors. (a,b) Cumulative probability plots of pixel intensity showing the effect of the NO donors SNP and DEA-NONOate (both at 100 \textmu M) on dye loading in HeLa cells expressing Cx26\textsuperscript{K125C} or wild-type Cx26 (Cx26\textsuperscript{WT}) compared with the control, and the effect of zero Ca\textsuperscript{2+}. The donors do not cause dye loading in HeLa cells expressing Cx26\textsuperscript{WT}, but do in HeLa cells expressing Cx26\textsuperscript{K125C}—as shown by rightward shift of cumulative probability plots. The cumulative probability plots are from combined data for five independent repetitions of each condition. Inset shows the median change in median pixel intensity (n = 5) for the actions of DEA-NONOate and SNP (100 \textmu M) on Cx26\textsuperscript{K125C} and Cx26\textsuperscript{WT}. (c) A lower dose of DEA-NONOate (10 \textmu M) causes a smaller amount of dye loading compared with the zero Ca\textsuperscript{2+} control. The dye loading is unaffected by the guanylate cyclase inhibitor ODQ (3 \textmu M). (d) Summary histogram showing the median change in median pixel intensity caused by 10 \textmu M DEA-NONOate either on its own or with 3 \textmu M ODQ (n = 5, p = 0.421, Mann–Whitney U-test).

HeLa cells expressing Cx26\textsuperscript{K125C} responded to 100 \textmu M NO\textsubscript{2}\textsuperscript{-} (figure 7a,b). Interestingly, this response was some 20 times slower in onset than the response of wild-type Cx26 to CO\textsubscript{2} (figure 7c). HeLa cells expressing Cx26\textsuperscript{K125C,R104C} exhibited a slow conductance increase when exposed to BSO (figure 7c,d). When transferred to NAC, the conductance increase initially accelerated before diminishing back towards the previous baseline (figure 7c). This initial acceleration of the conductance change may be due to the continued presence of BSO inside the cell, and the time required to wash it out, before the depleted intracellular glutathione levels can be replenished sufficiently to reduce intracellular redox and thus close the hemichannel.

Interestingly, removal of NAC revealed a slow and reversible conductance increase, suggesting that the native redox state of the HeLa cells is slightly oxidized compared with the highly reduced state induced by inclusion of NAC (figure 7e,d). The increase in conductance following removal of NAC also had a time constant some 20 times slower than the response of wild-type Cx26 to CO\textsubscript{2} (figure 7c).

The residue 125 is near the intracellular loop and thus on the cytoplasmic side of the plasma membrane. The dynamics of hemichannel opening will therefore result from a combination of how quickly the agonist can permeate into the cell to reach the binding site on residue 125 and the propensity for the covalent reaction at residue 125 to occur. For the redox sensitivity, there is the additional complication that NAC and BSO act indirectly to change the intracellular concentration of glutathione, which then alters intracellular redox...
state to either make or break the disulfide bridge between C125 and C104 of adjacent subunits. It is therefore not surprising that the new agonist sensitivities that we have introduced into the mutated channels have considerably slower kinetics than the native sensitivity to CO₂. Nevertheless, our results with BSO and NAC imply that glutathione metabolism is highly dynamic within the HeLa cells and is consistent with other observations of glutathione synthesis in these cells [12].

5. Discussion

To the best of our knowledge, this is the first time that novel agonist sensitivity has been introduced into connexin hemichannels. With our hypothesis-driven mutational strategy, we have converted wild-type Cx26 from a CO₂-sensitive hemichannel to an NO/NO₂-sensitive hemichannel in Cx26K125C, and a redox-sensitive hemichannel in Cx26K125C,R104C (figure 1). Crucially, wild-type Cx26 hemichannels do not exhibit sensitivity to either NO donors, NO₂⁻ or intracellular redox. This contrasts with some other connexin and pannexin hemichannels that can be regulated by NO and intracellular redox [13–15]. Our results are important in two respects. First, they provide further support for our hypothesis that bridges involving residues 125 and 104 of adjacent subunits can gate the opening of Cx26 [5]. By introducing mechanistically different bridges at the same location in the protein, we have shown that alternative agonists can open the hemichannel, providing they promote inter-subunit bridge formation between residues 125 and 104, even if this is via a different mechanism. Second, our new evidence further strengthens the concept of hemichannels as agonist-gated channels somewhat analogous to ligand-gated receptors. In a traditional ligand-gated receptor,
the ligand binds and elicits a conformational change, which allows ion flow through the receptor channel. For hemichannels, the ligand or agonist binds to cause conformational change, and the opening of the hemichannel allows the fluxes of small molecules in addition to ions. ATP, an important physiological signalling molecule in many organ systems including the brain, is known to permeate connexin hemichannels [4,16,17]. Cx26 and related β connexins, which are opened by CO2 [4,5,8], and other hemichannels such as Cx37, Cx40 and Cx43, which are opened by NO [18], therefore provide mechanisms for physiologically important ligand-gated ATP release.

In wild-type Cx26, the available crystal structure [19] suggests that K125 and R104 of adjacent subunits are only about 6 Å apart. Once carbamylation has occurred this distance would fall to about 7–8 Å [16,17]. Once carbamylation has occurred this distance would fall to about 7–8 Å. A CO2 stimulus given to the Cx26WT cells acted as a positive control to demonstrate functional hemichannels in these cells. (Figure 7ab) Comparison of effect of 100 μM NO2 on HeLa cells expressing Cx26WT and Cx26K125C. NO2− has no effect on the cells expressing Cx26WT, but causes a slow and reversible whole cell conductance increase in cells expressing Cx26K125C. Voltage clamp recordings were performed with a holding potential of −40 mV and repeated voltage steps to −50 mV. The size of the current deflection during the voltage step indicates the whole cell conductance. A CO2 stimulus given to the Cx26WT cells acted as a positive control to demonstrate functional hemichannels in these cells. (c) Comparison of the effect of altering intracellular redox potential of HeLa cells expressing Cx26WT or Cx26K125C,R104C. Changes in redox potential had no effect on the cells expressing the wild-type hemichannels (CO2 stimulus as a positive control). However, in cells expressing the double mutant Cx26K125C,R104C, large reversible increases in whole cell conductance were seen during treatment with BSO and NAC. In cells exposed to NAC, the removal of NAC resulted in a small conductance increase reflecting the difference between the endogenous redox state of the cells and the very reduced state in the presence of NAC. (d) Comparison of the mean conductance change of the redox stimulus in the wild-type (WT redox) and Cx26K125C,R104C expressing HeLa cells. For the Cx26K125C,R104C expressing HeLa cells: BSO redox is the whole cell conductance change measured during BSO washout with NAC, and endog redox is the whole cell conductance observed on NAC washout. (e) Comparison of the time constant of the increase in whole cell conductance. Current records were fitted with the equation A[1 − exp(−t/τ)] + B, where A and B are constants to appropriately scale the curve to the observed records and τ is the time constant for the change in membrane current. This revealed that the changes evoked by CO2 had a mean time constant of around 5 s, whereas those evoked in Cx26K125C and Cx26K125C,R104C, respectively, by NO2− (K125C NO2−) and washout of NAC (CC NAC wash) were some 20 times slower. Error bars represent the s.e.m.
this would be too far for interaction between the SNO group and R104. Similarly, in Cx26K125SC,R104C the two introduced cysteine residues would be nearly 16 Å apart—a gap far too large for disulfide bridge formation. Nevertheless, our data strongly suggest the formation of an SNO bridge between C125 and R104, and a disulfide bridge between C125 and C104. This implies considerable flexibility in the protein so that these residues can come into sufficient proximity to allow interaction and bond formation. Our elastic network models [5] based on the crystal structure [19] suggest that Cx26 is highly flexible with harmonic motions of the major alpha helices that could bring these residues into close apposition and permit bond formation. These data therefore provide additional support for our previous elastic network models. The large distance of these interactions may also contribute to their slow formation, and be an additional reason why NO$_3^-$ and intracellular redox cause rather slow channel opening.

Finally, we have generated molecules with new functionality that can, respectively, give NO/NO$_2^-$ and intracellular redox-mediated ATP release. The closest precedent to this change of agonist specificity for a receptor is the creation of the DREADD receptors from the muscarinic receptor [20]. DREADD receptors can be opened by the synthetic agonist clozapine-N-oxide, and have been highly useful analytical tools to test the roles of neuronal populations [21,22]. Our modified Cx26 hemichannels may conceivably be useful in the analysis and perturbation of NO and redox signalling.
